Review: Data structures in Python

Reference guide: Lists

You've been learning that lists are important data structures in Python. A list is a data structure that helps store and manipulate an ordered collection of items. These items can be of any data type such as integers, floats, strings, and even other lists. Because they are so versatile, data professionals and all Python programmers use lists every day, so it's important to be familiar with how they work. This reading is a reference guide for lists designed to help you as you learn Python.

Create a list

There are two main ways to create lists in Python:

- Square brackets: `[]`
- The list function: `list()`

When instantiating a list using brackets, separate each element with a comma.

For example, the following code creates a list of strings:

```
1 list_a = ['olive', 'palm', 'coconut']
2 print(list_a)
```

Run

Reset

You can also create a list of integers:

```
1 list_b = [8, 6, 7, 5, 3, 0, 8]
2 print(list_b)
```

Run

Reset

Or a list of mixed data types:

```
1 list_c = ['Abdijan', 14.2, [1, 2, None], 'Zagreb']
2 print(list_c)
```

Run

Reset

To create an empty list, use empty brackets or the `list()` function:

```
1 empty_list_1 = []
2 empty_list_2 = list()
```

Run

Reset

Indexing and slicing

Just as with strings, you can access elements in a list using indexing and slicing. The first element of a list has index zero, the second element has index one, and so on. Use square brackets to index:

```
1 phrase = ['Astra', 'Inclement', 'sed', 'non', 'obligant']
2 print(phrase[1])
```

Run

Reset

You can also use negative indices to access items from the end of a list:

```
1 phrase = ['Astra', 'Inclement', 'sed', 'non', 'obligant']
2 print(phrase[-2])
```

Run

Reset

Use slicing to extract a sublist. To slice, use square brackets containing a range of indices separated by a colon:

```
1 phrase = ['Astra', 'Inclement', 'sed', 'non', 'obligant']
2 print(phrase[1:4])
```

Run

Reset

Notice that this code returned a sublist containing the elements at indices one, two, and three of phrase. The ending index of the slice is not included.

Omitting the starting index in a slice implies an index of zero, and omitting the ending index implies an index of `len(my_list)`:

```
1 phrase = ['Astra', 'Inclement', 'sed', 'non', 'obligant']
2 print(phrase[:3])
3 print(phrase[3:])
```

Run

Reset

List mutability

Lists are mutable, which means that you can change their contents after they are created. You can change an individual item in a list by specifying its index and assigning a new value to it. For example:

```
1 my_list = ['Macduff', 'Malcolm', 'Duncan', 'Banquo']
2 my_list[2] = 'Macbeth'
3 print(my_list)
```

Run

Reset

You can even change a slice of a list using the same logic. The slice can be of any length. The elements in the new list will be inserted in place of the indicated slice:

```
1 my_list = ['Macduff', 'Malcolm', 'Macbeth', 'Banquo']
2 my_list[1:3] = [1, 2, 3, 4]
3 print(my_list)
```

Run

Reset

List operations

Lists can be combined using the addition operator (+):

```
1 num_list = [1, 2, 3]
2 char_list = ['a', 'b', 'c']
3 num_list + char_list
```

Run

Reset

They can also be multiplied using the multiplication operator (*):

```
1 list_a = ['a', 'b', 'c']
2 list_a * 2
```

Run

Reset

But they cannot be subtracted or divided.

You can check whether a value is contained in a list by using the `in` operator:

```
1 num_list = [2, 4, 6]
2 print(5 in num_list)
3 print(5 not in num_list)
```

Run

Reset

List methods

Lists are a core Python class. As you've learned, classes package data together with tools to work with it. Methods are functions that belong to a class. Lists have a number of built-in methods that are very useful.

append ()

Add an element to the end of a list:

```
1 my_list = [0, 1, 1, 2, 3]
2 variable = 5
3 my_list.append(variable)
4 print(my_list)
```

Run

Reset

insert ()

Insert an element at a given position:

```
1 my_list = ['a', 'b', 'd', 'e']
2 my_list.insert(2, 'c')
3 print(my_list)
```

Run

Reset

remove ()

Remove the first occurrence of an item:

```
1 my_list = ['a', 'b', 'd', 'a']
2 my_list.remove('a')
3 print(my_list)
```

Run

Reset

pop ()

Remove the item at the given position in the list, and return it. If no index is specified, `pop()` removes and returns the last item in the list:

```
1 my_list = ['a', 'b', 'c']
2 print(my_list.pop())
3 print(my_list)
```

Run

Reset

clear ()

Remove all items:

```
1 my_list = ['a', 'b', 'c']
2 my_list.clear()
3 print(my_list)
```

Run

Reset

index ()

Return the index of the first occurrence of an item in the list:

```
1 my_list = ['a', 'b', 'c', 'a']
2 my_list.index('a')
```

Run

Reset

count ()

Return the number of times an item occurs in the list:

```
1 my_list = ['a', 'b', 'c', 'a']
2 my_list.count('a')
```

Run

Reset

sort ()

Sorts the list ascending by default. You can also make a function to decide the sorting criteria:

```
1 char_list = ['b', 'c', 'a']
2 num_list = [2, 3, 1]
3 char_list.sort()
4 num_list.sort(reverse=True)
5 print(char_list)
6 print(num_list)
```

Run

Reset
